1.

First we compute the proportion of infected population with assumption $s_0 = 1$:

$$s(\infty) - s(0) = \frac{log(s(\infty))}{R_0}, s(0) = 1, R_0 = 3$$

$$s(\infty) = \frac{log(s(\infty))}{3} + 1$$

Then we have $S(\infty) = 0.05962$. Thus there are in total 178560 people being infected. By multiplying a death rate of 2% we know there are 3571.2 expected death cases.

2.

First we compute $i_m ax$:

$$i_m ax = 1 - \frac{1}{R_0} - \frac{log(R_0)}{R_0}$$

$$i_m ax = 1 - \frac{1}{3} - \frac{ln(3)}{3}$$

Then we have $i_m ax$ is approximately 0.3. Thus there are in total 900000 patients at the peak. Since there are 1000000 hospitals beds and only 50% are available and only 20% of the patiences need a bed. There are in total $900000 * 0.2 - 10000000 \times 0.5 = -320000$ extra beds needed. Which means everyone gets a bed.

3.

We compute R_0 using:

$$R_0 = \frac{log(\frac{s(\infty)}{s(0)})}{s(\infty) - s(0)}$$

$$R_0 = \frac{log(\frac{0.4)}{0.9})}{0.4 - 0.9}$$

Thus we get $R_0 \approx 1.6218$.
